Key Points:

- Multi-spacecraft observations of the Sun from the Sun-Earth Lagrange points L1, L4 and L5 can provide a clear and wide-angle view to investigate the Sun-Earth, Sun-Moon and Sun-Mars connections
- Visibility of the solar surface is analyzed based on remote-sensing observations from single (L1), double (L1 and L4) and multi-space missions (L1, L4 and L5)
- A quantitative comparison of the solar surface visibility is made in the context of (1) observation days per year for a given solar latitude, (2) continuous tracking of a target feature (e.g., sunspots) on the solar disk, and (3) a chance of observing a limb flare from one spacecraft and its on-disk counterpart from the others

Abstract

Beyond the Sun-Earth line, spacecraft equipped with various solar telescopes are intended to be deployed at several different vantage points in the heliosphere to carry out coordinated, multi-view observations of the Sun and its dynamic activities. In this context, we investigate solar visibility by imaging instruments onboard the spacecraft orbiting the Sun-Earth Lagrange points L1, L4, and L5, respectively. An optimal arrival time for vertical periodic orbits stationed at L4 and L5 is determined based on geometric considerations that ensure maximum visibility of solar poles or higher latitudes per year. For a different set of orbits around the three Lagrange points (L1, L4, and L5), we calculate the visibility of the solar surface (i.e., observation days per year) as a function of the solar latitude. We also analyze where the solar limb viewed from one of the three Sun-Earth Lagrange points under consideration is projected onto the solar surface visible to the other two. This analysis particularly aims at determining the feasibility of studying solar eruptions, such as flares and coronal mass ejections, with coordinated observations of off-limb erupting coronal structures and their on-disk magnetic footpoints. In addition, visibility analysis of a feature (such as sunspots) on the solar surface is made for multiple spacecraft in various types of orbits with different inclinations to quantify the improvement in continuous tracking of the target feature for studying its long-term evolution from emergence, growth and to decay. A comprehensive comparison of observations from single (L1), double (L1 and L4), and multi-space missions (L1, L4 and L5) is carried out through our solar visibility analysis, and this may help us to design future space missions of constructing multiple solar observatories at the Sun-Earth Lagrange points.

Plain Language Summary

Scientists plan to send more spacecraft equipped with many scientific payloads beyond the line connecting the Sun and Earth. These spacecraft will be strategically positioned to observe the Sun and its activities from multiple perspectives. We specifically focus on studying the visibility of the Sun from spacecraft located at the Sun-Earth Lagrange points L1, L4, and L5, where the gravity of the Earth and Sun allow the spacecraft to remain over long periods of time. To optimize observations, we determine the best times for spacecraft stationed at Lagrange points L4 and L5. This decision is based on geometric considerations to maximize the visibility of the solar poles and higher latitudes throughout the year. Additionally, we examine how the solar limb, the Sun's outer edge, appears when viewed from one Lagrange point. This analysis helps us to understand the possibility of studying solar eruptions, such as flares and coronal mass ejections, by coordinating observations of erupting coronal structures and their footprints on the solar disk. Furthermore, we assess the visibility of specific features, like sunspots, on the solar surface for multiple spacecraft in different types of orbits with varying inclinations. This analysis helps us quantify the improvement in continuously tracking these features, allowing us to study their long-term evolution from emergence and growth to decay.

1 Introduction

The Sun consistently blows out the high-speed solar wind into interplanetary space and occasionally produces large eruptive events such as flares, solar energetic particles (SEPs) and coronal mass ejections (CMEs). When such dynamic solar activities occur, they may cause heliospheric disturbances and consequently affect the so-called space weather (e.g., Schwenn, 2006; Vourlidas, 2021; Temmer, 2021; Zhang et al., 2021). The magnetic field of the Sun is fundamental to understanding the origin, structure and dynamics of the solar wind (e.g., Wang et al., 2000; Antiochos et al., 2011) as well as the trigger mechanism of solar eruptions (e.g., Park et al., 2010; Kusano et al., 2012). It is therefore important to acquire information on the dynamic solar activity and magnetic field extended to the heliosphere with remote-sensing observations as precisely, immediately and extensively as possible. There

69 have been, however, limitations to obtaining such information due to the observations mostly
70 carried out from the Sun-Earth line (i.e., from ground telescopes, Earth-orbiting satellites, or
71 spacecraft at the Sun-Earth Lagrange point L1). To overcome this limited view of the Sun,
72 various space missions are currently in operation (e.g., Parker Solar Probe, Solar Orbiter,
73 STEREO-A) and in preparation (e.g., ESA’s Vigil at the Sun-Earth Lagrange point L5) off
74 the Sun-Earth line, thereby carrying out coordinated, multi-view observations of the Sun.

75 The Sun-Earth Lagrange points (hereafter, simply refer to as L1–L5), especially the
76 triangular points L4 and L5, are viable options for observing the Sun from multiple angles
77 (Cho et al., 2023; Moon et al., 2024). Observations made through remote sensing, spanning
78 heliographic longitudes up to 120° apart between L4 and L5, provide visibility coverage for
79 a substantial portion (i.e., 300° of longitude as the maximum meridional extent allowed) of
80 the solar surface at any given time. This effectively reduces any observational blind spots on
81 the solar surface. Such wide-view coverage is pivotal for real-time monitoring of the Sun,
82 improving the capability to detect and monitor solar eruptive events and predict their impact
83 on the heliospheric environment. As shown in Figure 2, remote-sensing observations from
84 L4, together with L1, can help to carry out a thorough investigation of solar source regions
85 that produce SEPs. The wider field of view for solar observations also enables the longer
86 tracking of a feature of interest, which will help us to understand its persistent evolution as
87 it rotates: e.g., emergence, development and decay of sunspots (e.g., van Driel-Gesztelyi &
88 Green, 2015).

89 The strategic positioning of spacecraft at the multiple Sun-Earth Lagrange points will
90 provide an advantage in reconstructing the three-dimensional (3D) structure of CMEs and
91 determining their propagating direction and speed from stereoscopic observations. These
92 multiple viewpoints can also contribute to resolving an intrinsic 180° ambiguity in the
93 orientation of the transverse magnetic field present in Zeeman effect measurements on the
94 surface, as discussed in Posner et al. (2021); Valori et al. (2023); Cho et al. (2023); Moon
95 et al. (2024). In addition, a combination of solar on-disk and off-limb observations for
96 the same target region by this multi-spacecraft configuration will be beneficial for a better
97 understanding of solar eruptions, allowing us more comprehensive modeling of their magnetic
98 field structure and evolution in the 3D solar atmosphere (i.e., through multiple layers from
99 the photosphere to the corona).

100 A unique perspective to precisely observe the Sun’s high latitudes can be achieved by
101 optimizing the design of vertical periodic orbits for spacecraft at L4 and L5, reducing the
102 projection effect on solar image data. The polar and high-latitude region of the Sun is of
103 particular interest because the magnetic field strength in such region around the minimum
104 of the 11-year solar activity cycle has a close relation with the sunspot number at the
105 upcoming maximum (e.g., Schatten et al., 1978; Pesnell, 2012; Javaraiah, 2023). One can
106 accurately measure solar meridional flows at high latitudes (toward the polar region), which
107 are thought to play an important role in weakening the Sun’s polar magnetic fields and
108 eventually changing their polarity (e.g., Hathaway & Rightmire, 2010; Nandy et al., 2011;
109 Lekshmi et al., 2019).

110 This paper is structured in the following manner. In Section 2, we first introduce periodic
111 orbits associated with the Sun-Earth system’s first (L1), fourth (L4), and fifth (L5) Lagrange
112 points based on the dynamics of the Circular-Restricted Three-Body Problem (CRTBP).
113 Section 3 presents our methodology for analyzing solar visibility. Section 4 discusses the
114 visibility analysis results using a single spacecraft at L1 point and multiple spacecraft at
115 L1, L4, and L5 points for various observation missions (e.g., on-disk observation, solar limb
116 observation, and continuous Sun spot observation). Section 5 summarizes the study and
117 discussions for future studies.

Figure 1: Cartoon showing solar surface visibility with three spacecraft positioned at the Sun-Earth Lagrange points L1, L4 and L5 on the Stonyhurst heliographic coordinate system (panel a) and on the spherical surface of the Sun (panel b). The visible solar surface by an imaging instrument (with a viewing angle of 40° toward the center of the Sun) onboard each of the spacecraft is shown in blue, red and green, respectively, for L1, L4 and L5, while the invisible region in gray. The region visible by two spacecraft is denoted in magenta for L1 and L4, while in cyan for L1 and L5. The white line represents the solar limb viewed from each of the spacecraft.

Figure 2: Illustration of the solar radiation hemisphere that is the relative solar hemisphere from a 1 AU observer at the Earth with possessing the potential to severely affect the radiation environment at or near the Earth. It ranges from 30°E to 150°W in solar longitudes and is best observed from L4. A histogram from Richardson et al. (2014) displays source longitudes of major solar proton events in the energy range of 14–24 MeV. Highlighted are the Earth-Moon system, Hohmann transfer orbits to and from Mars, L4 and L5, and an interplanetary magnetic field line from 60°W on the Sun to the Earth modeled from an average solar wind speed in the ecliptic plane. This figure is adapted from Posner et al. (2021).

2 Orbits around the Sun-Earth Lagrange points

2.1 Circular Restricted Three-body Problem

The Circular Restricted Three-Body Problem (CRTBP) governs the motion of a massless spacecraft influenced by the gravitational attraction of two large masses. In the case of the Sun-Earth system, the origin of the CRTBP rotating frame is located at the barycenter of the two masses. The x-axis consistently points from the system's primary to the secondary masses (i.e., from the Sun to the Earth). The z-axis aligns with the secondary body's angular momentum vector. Employing canonical units in Table 1 for dimensionless quantities as well as setting the angular velocity of the primary and secondary with respect to the barycenter as unity, the governing CRTBP equations are defined with the position vector $\mathbf{r} = [x, y, z]$ and the velocity vector $\mathbf{v} = [v_x, v_y, v_z]$, as follows:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) = \left[v_x, v_y, v_z, 2v_y + \frac{\partial \Omega}{\partial x}, -2v_x + \frac{\partial \Omega}{\partial y}, \frac{\partial \Omega}{\partial z} \right]. \quad (1)$$

The potential function Ω is defined as:

$$\Omega(\mathbf{r}) = \frac{x^2 + y^2}{2} + \frac{1 - \mu}{r_1} + \frac{\mu}{r_2} \quad (2)$$

where $\mu = \frac{m_2}{m_1 + m_2}$, and the positions of the spacecraft measured from the primary and secondary masses are given by $r_1 = \sqrt{(x + \mu)^2 + y^2 + z^2}$ and $r_2 = \sqrt{(x - 1 + \mu)^2 + y^2 + z^2}$, respectively (Vallado, 2001). The CRTBP dynamical system features a conserved integral known as the Jacobi integral (C):

$$C = 2\Omega - (v_x^2 + v_y^2 + v_z^2). \quad (3)$$

The Jacobi integral C determines the so-called Hill's region, which, in turn, defines the allowable region of motion in the rotating frame for a given energy level. More on the Jacobi's integral on the trajectories near the periodic orbits can be found in Lee & Ahn (2021, 2022, 2024); Lee et al. (2023).

2.2 Periodic Orbits of the Sun-Earth Lagrange Points

In the context of CRTBP, periodic orbits appear as a distinctive trajectory circumnavigating the Lagrange points. When represented within the rotating frame, these orbits manifest as recurrent, ensuring that the spacecraft's position and velocity return to their initial conditions. The stability of these periodic orbits is intrinsically linked to that of the corresponding Lagrange points. Periodic orbits around L1, L2 and L3 are unstable, while those around L4 and L5 are stable (Vallado, 2001). An infinite spectrum of periodic orbits exists, each distinguished by its unique Jacobi integral. Among multiple families of periodic orbits, planar Lyapunov periodic orbits around L1 are presented in Figure 3, which are symmetric with respect to the x-axis (Thurman & Worfolk, 1996). Meanwhile, Figure 4 shows planar and vertical Lyapunov periodic orbits around L4 at different energy levels. As the Jacobi integral decreases, both L1 and L4 Lyapunov orbits increase amplitudes in the x- and y-directions. Similarly, the lower value of the Jacobi integral corresponds to the larger amplitude in the z-direction for L4's vertical periodic orbits. We note that these characteristics of L4's periodic orbits remain the same for L5.

As suggested by its name, the planar Lyapunov orbit family has a consistent zero inclination across its orbits (i.e., lying in the x-y plane) with respect to the ecliptic plane. At the same time, there is a noticeable increase in eccentricity and a decrease in the semi-major axis as the Jacobi integral decreases. On the other hand, vertical periodic orbits, passing through the triangular Lagrange point (L4 or L5) twice a year, maintain an osculating semi-major axis of 1 AU and zero eccentricity. The orbital period of the periodic orbit varies

Table 1: Non-dimensional canonical unit of the Sun-Earth CRTBP system

Unit	Value
Time (TU)	5.0226757E6 seconds
Distance (AU)	1.4959965E8 km
Velocity (VU)	29.7849 km/s

159 slightly depending on the C level. Nevertheless, it's crucial to highlight that the orbital
 160 period plays a less significant role for spacecraft orbiting around the Lagrange points as
 161 they synchronize with the Earth. Out of numerous periodic orbits, this study specifically
 162 focuses on (1) the planar Lyapunov periodic orbit around L1 with $3.0001 \leq C \leq 3.001$, (2)
 163 the planar Lyapunov periodic orbit around L4 (or L5) with $2.96 \leq C \leq 2.999$, and (3) the
 164 vertical periodic orbits around L4 (or L5) with $2.88 \leq C \leq 2.999$.

Figure 3: Planar Lyapunov periodic orbits at the Sun-Earth Lagrange point L1 are shown with a different set of values for the Jacobi integral.

Figure 4: Planar and vertical Lyapunov periodic orbits at L4 are shown with a different set of values for the Jacobi integral. For the vertical periodic orbits, the one with an inclination of 14.5° with respect to the ecliptic plane is marked in red.

3 Methods for Solar Visibility Analysis

3.1 Definition of Solar Visibility Conditions

In this analysis of solar surface visibility, the heliographic inertial frame (HGI) serves as the appropriate coordinate system for determining the latitude and longitude coverage of the solar surface, as depicted in Figure 5a. The x-y plane of the HGI frame is defined as the solar equatorial plane, and the z-axis (i.e., the solar rotation axis) is inclined at 7.25° relative to the z-axis of the ecliptic coordinate system. The HGI's x-axis is directed along the intersection line of the ecliptic and solar equatorial planes (Thompson, 2006), where the ecliptic longitude of the Sun's ascending node is 75.77° (J2000).

This study incorporates the corrected oblateness of the non-magnetic Sun, quantified as 8.01 ± 0.14 milli-arcseconds or equivalently 2.225×10^{-6} degrees (Dicke, 1974; Rozelot et al., 2001). The variance of ± 0.14 milli-arcseconds is omitted in the visibility analysis. The solar surface represented by the spherical grid in Figure 5 is segmented into the grid cells of which each has longitudinal and latitudinal extents of 5° and 6° , respectively. In Section 4.4, when analyzing the sunspot visibility, the differential rotational rate $\dot{\omega}(\phi)$ of the Sun is modeled as follows:

$$\dot{\omega}(\phi) = A + B \sin^2(\phi) + C \sin^4(\phi), \quad (4)$$

where $A = 14.713 \pm 0.0491^\circ/\text{day}$, $B = -2.396 \pm 0.188^\circ/\text{day}$, $C = -1.787 \pm 0.253^\circ/\text{day}$, and ϕ denotes the heliographic latitude (positive/negative towards the North/South) measured from the solar equator (Snodgrass & Ulrich, 1990).

Figure 5: Definition of the heliographic inertial coordinate system (HGI) with respect to the ecliptic coordinate system (E). In panel (b), Θ_{ij}^t is an angle between the surface normal vector \mathbf{n}_{ij} and the line-of-sight vector \mathbf{R}_{LOS}^t at time t of observations by an instrument onboard a spacecraft.

The solar surface visibility condition is determined with the so-called position angle Θ_{ij}^t , defined as:

$$\Theta_{ij}^t = \cos^{-1} \left(\frac{\mathbf{n}_{ij} \cdot \mathbf{R}_{LOS}^t}{|\mathbf{n}_{ij}| |\mathbf{R}_{LOS}^t|} \right), \quad (5)$$

where \mathbf{n}_{ij} is the normal vector of the grid cell on the surface with the i 'th and j 'th heliographic latitude and longitude, respectively. \mathbf{R}_{LOS}^t is defined as the line-of-sight (LOS) vector of an imaging instrument onboard a spacecraft from the center of the Sun at t . As shown in figure 5b, Θ_{ij}^t is an angle between \mathbf{n}_{ij} and \mathbf{R}_{LOS}^t at time t of observations. It is assumed in this analysis that the given spacecraft at the Sun-Earth Lagrange points performs perfect attitude control to keep the LOS vector \mathbf{R}_{LOS}^t persistently directed to the center of the Sun.

Figure 6: Demonstration of how the projection effect degrades a solar image obtained by remote-sensing observations. In panel (a), (right) an image of the radial component B_r of the Sun’s photospheric magnetic field obtained by SDO/HMI is shown, and (left) its field-of-view is marked with the white box in the full solar disk. We note that Θ_{ij}^t is 0° at the center of the cutout image. In panel (b), (right) the same cutout image of B_r in panel (a) is remapped as simply locating the field-of-view to a higher latitude of 60°N but the same longitude.

192 For images obtained from remote-sensing observations, a feature located in (i, j) on the
 193 solar surface can be severely affected by the so-called projection effect depending on Θ_{ij}^t . For
 194 example, the physical length of the feature on the solar surface are scaled by $1/\cos\Theta_{ij}^t$. In
 195 Figure 6, we demonstrate the projection effect using an image of the radial component B_r of
 196 the Sun’s photospheric magnetic field obtained by the Helioseismic and Magnetic Imager
 197 (HMI) onboard the Solar Dynamics Observatory (SDO). The right panel of Figure 6(a)
 198 shows a cutout image of B_r at 16:00 TAI on 2020-07-23, of which the field-of-view is marked
 199 with the white box in the left panel. We note that Θ_{ij}^t is 0° at the center of the cutout
 200 image. In Figure 6(b), the same cutout image in Figure 6(a) is remapped as simply locating

201 the field-of-view to a higher latitude of 60°N but the same longitude. The image quality
 202 degrades as small-scale magnetic features on the solar surface become smoothed or their fine
 203 structures are unresolved due to the projection effect. Depending on science objectives and
 204 data requirements, it is required to investigate how critical the projection effect will impact
 205 images obtained from remote-sensing observations. In this context, given Θ_{ij}^t , we determine
 206 the condition of the solar surface visibility (i.e., "good enough" to be used as scientific data
 207 or not), considering a different set of values for the maximum angle Θ_{\max} allowed for on-disk
 208 observations as follows.

$$\psi_{ij}^t = \begin{cases} 1 & \text{if } \Theta_{ij}^t < \Theta_{\max} \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

209 Here ψ_{ij}^t is the element of the instantaneous visibility matrix at time t . For limb observations,
 210 both Θ_{\max} and the minimum angle Θ_{\min} are considered.

$$\psi_{ij}^t = \begin{cases} 1 & \text{if } \Theta_{\min} < \Theta_{ij}^t < \Theta_{\max} \\ 0 & \text{otherwise} \end{cases} \quad (7)$$

211 To determine the duration of the solar surface visibility per orbital period, ψ_{ij}^t is then
 212 (1) multiplied with the simulation time step δt of 2 hours, (2) summed over all simulation
 213 times of $T = \{t_0, t_1, \dots, t_N\}$ during the period τ of each orbit considered at the Sun-Earth
 214 Lagrange points (i.e., $\tau = t_N - t_0 = 1$ year), and (3) divided by τ :

$$\Psi_{ij} = \frac{\sum_{t \in T} \psi_{ij}^t \cdot \delta t}{\tau}. \quad (8)$$

215 Here, Ψ_{ij} represents the visibility duration of the heliographic coordinates (i, j) per orbital
 216 period with the unit of days per year. For a given latitude i , as calculating the average of
 217 Ψ_{ij} values over all longitudes, we can determine the mean visibility duration $\bar{\Psi}_i$ as a function
 218 of latitude:

$$\hat{\Psi}_i = \frac{\sum_j \Psi_{ij}}{N_j}, \quad (9)$$

219 where N_j is the total number of longitudinal grid points.

220 To analyze sunspot visibility, we define a single grid cell located at a heliographic latitude
 221 ϕ and longitude of 0° in the simulation coordinate system at t_0 as a test sunspot. The test
 222 sunspot is set to rotate at a constant speed governed by the differential rotation described in
 223 Equation 4 and stays on the solar surface over the simulation period τ . The normal vector
 224 $\mathbf{n}_{\text{spot}}(t, \phi)$ of the test sunspot cell is then represented as follows:

$$\mathbf{n}_{\text{spot}}(t, \phi) = \mathcal{R}(\mathbf{z}_{HGI}, \dot{\omega}(\phi) \cdot \Delta t) \mathbf{n}_{\text{spot}}(t_s, \phi), \quad (10)$$

225 where $\mathcal{R}(\mathbf{z}_{HGI}, \dot{\omega}(\phi) \cdot \Delta t)$ is the rotation matrix of the sunspot over a time span of Δt from
 226 t_0 . The rotation matrix is defined as:

$$\begin{aligned} \mathcal{R}(\mathbf{z}_{HGI}, \dot{\omega}(\phi) \cdot \Delta t) &= \cos(\dot{\omega}(\phi) \cdot \Delta t) I_{3 \times 3} + \sin(\dot{\omega}(\phi) \cdot \Delta t) \mathbf{z}_{HGI}^\times \\ &+ [1 - \cos(\dot{\omega}(\phi) \cdot \Delta t)] \mathbf{z}_{HGI} \mathbf{z}_{HGI}^T, \end{aligned} \quad (11)$$

227 where \mathbf{z}_{HGI}^\times defines the skew matrix of \mathbf{z}_{HGI} . The mean visibility duration of the test
 228 sunspot per orbital period is determined with $\mathbf{n}_{\text{spot}}(t, \phi)$, applying the same criterion (i.e.,
 229 Equation 6) and the procedure (i.e., Equations 8 and 9) as used in the analysis of the solar
 230 surface visibility.

231

3.2 Setup for an Orientation of Vertical Periodic Orbits at L4 and L5

232

233

234

235

236

Posner et al. (2021) analyzed vertical periodic orbits at L4 and L5 to optimize the simultaneous view of high-latitude regions in both the northern and southern hemispheres of the Sun from remote-sensing observations at L1, L4, and L5 over a year. On the other hand, in this study, we aim to achieve a longer observation duration of high solar surface latitudes. In this context, we define α as 0° as:

$$\alpha = \begin{cases} \angle(\text{proj}_{\mathbf{E}}\mathbf{R}_+, \text{proj}_{\mathbf{E}}\mathbf{P}_N) & \text{for spacecraft at north of the ecliptic plane,} \\ \angle(\text{proj}_{\mathbf{E}}\mathbf{R}_-, \text{proj}_{\mathbf{E}}\mathbf{P}_S) & \text{for spacecraft at south of the ecliptic plane,} \end{cases} \quad (12)$$

237

238

239

240

241

242

243

244

245

246

247

where $\text{proj}_{\mathbf{E}}(\cdot)$ denotes the vector projection onto the ecliptic plane, $\mathbf{R}_{+/-}$ is the LOS vector of an imaging instrument onboard a spacecraft from the center of the Sun when the spacecraft is located at the highest/lowest point on the z-axis of the ecliptic coordinate system, and $P_{N/S}$ is the vector directed from the solar center to the north/south pole (refer to Figure 7). For a spacecraft orbiting at L4 (or L5) with $\alpha = 0^\circ$, \mathbf{R}_{LOS}^t of its onboard imaging instrument can reach the highest solar latitude (both in the north and south) that is the orbital inclination plus the tilt of 7.25° between the solar equator and the ecliptic plane. α is therefore set as 0° in all our visibility analysis. Figure 8 illustrates the time variation of the heliographic latitude for a given surface grid cell of which Θ_{ij}^t is 0° when viewed from spacecraft orbiting at L4 (or L5) with the same orbital inclination of 14.5° but deployed into the inclined orbit with a different set of α values.

Figure 7: When a spacecraft is located at north of the ecliptic plane, α is defined as an angle between the two vectors $\text{proj}_{\mathbf{E}}\mathbf{R}_+$ and $\text{proj}_{\mathbf{E}}\mathbf{P}_N$ projected onto the ecliptic frame. \mathbf{R}_+ is the LOS vector of an imaging instrument onboard a spacecraft from the center of the Sun when the spacecraft is located at the highest point on the z-axis of the ecliptic coordinate system, and P_N is the vector directed from the solar center to the north pole.

Figure 8: Time variation of the heliographic latitude for a solar surface grid cell with $\Theta_{ij}^t = 0^\circ$ viewed from four spacecraft orbiting around L4 (or L5) with the same inclination of 14.5° but different orientations (i.e., $\alpha = 0^\circ, 90^\circ, 180^\circ$ and 270° , respectively).

248 4 Results of Solar Visibility Analysis

249 4.1 Remote-sensing Observations from a Single Spacecraft

250 Except for the STEREO spacecraft, orbiting in an eccentric orbit around the Sun, most
 251 observations are located near the Sun-Earth line. For example, the ground telescopes on the
 252 surface of the Earth follow the Sun-Earth line, and the Heliosphere science-purposed satellites
 253 placed at GEO, LEO, and Sun-Earth L1 all follow the Sun-Earth line with a very minor
 254 position oscillation. The visibility duration of the solar surface with spacecraft (or ground
 255 telescopes on Earth's surface) placed near the Sun-Earth line is shown in Figure 9 as a function
 256 of latitude. The visibility analysis is performed with multiple $\Theta_{\max} = (40^\circ, 50^\circ, 60^\circ, 70^\circ)$,
 257 where the larger Θ_{\max} provides extended observation duration as expected. All of the visibility
 258 analysis performed in this section assumes optimal orbital orientation for maximum latitude
 259 visibility ($\alpha = 0$).

260 Unlike the orbits near the Sun-Earth line (LEO, GEO, Sun-Earth L1, and ground
 261 observatories), periodic orbits at L4 can possess large inclinations, as shown in Figure 4.
 262 Therefore, a similar trade-off study with that of a single spacecraft at L1 was performed
 263 for a single spacecraft placed at Sun-Earth L4 with varying inclinations with the same
 264 Θ_{\max} . The results are shown in Figure 10. The periodic orbit with a larger inclination
 265 enables the spacecraft to observe higher latitudes for an extended period. However, this
 266 comes at the expense of a shorter observation duration for latitudes closer to the Sun's
 267 equator. This phenomenon is a natural outcome of the spacecraft's oscillatory motion in the
 268 solar surface's latitudinal direction. The visibility duration characteristics remain consistent
 269 as Θ_{\max} increases until $\Theta_{\max} = 70^\circ$ where the observation trend deviates. As depicted in
 270 Figure 10d, a spacecraft at the triangular Lagrange point with an 18° inclination can observe
 271 latitudes of 90° for a longer duration than latitudes between 70° and 80° . This phenomenon
 272 arises from the spacecraft's capability to observe beyond the pole. Through this analysis,
 273 critical mission requirements and constraints can be determined. For instance: 1) given Θ_{\max}
 274 (from an optical camera) and the desired solar surface latitude to observe, what should be
 275 the inclination of the L4 periodic orbit to achieve observation for "X" number of days per

Figure 9: Solar surface visibility analysis for satellite oscillating near the Sun-Earth line with varying Θ_{max} . ϕ defines solar latitude, Θ_{max} defines the maximum allowable angle.

276 year? and 2) given the inclination of the L4 periodic orbit, what is the expected data quality
 277 at the desired latitude of the solar surface?

278 4.2 Synergy of Multi-Point On-Disk Observation

279 Multi-point observation has become a pivotal objective for the heliospheric science
 280 division of space agencies. Various white papers (Posner et al. (2021); Gopalswamy et al.
 281 (2023); Posner et al. (2023); Han et al. (2023); Cho et al. (2023)) have been authored to
 282 propose the design of a multi-view observatory spacecraft system situated near the triangular
 283 Lagrange point and the first Lagrange point. This configuration aims to enable access to a
 284 larger longitude range of the solar surface for an extended duration and from multiple angles.
 285 As indicated by Gopalswamy et al. (2023), observing the solar surface from multiple angles
 286 offers insights to address numerous fundamental questions in heliophysics research. Some of
 287 these unanswered questions include:

- 288 1. How do active regions evolve before and after emerging to the solar surface?
- 289 2. How do coronal mass ejections (CME) flux ropes form, accelerate, drive shocks, and
 290 evolve from near the Sun into the heliosphere, including particle acceleration?
- 291 3. How do corotating interaction regions (CIR) magnetic fields evolve in the inner
 292 heliosphere and accelerate particles?
- 293 4. How does shock geometry and magnitude evolve and how does this relate to solar
 294 energetic particles (SEPs) and radio bursts?
- 295 5. Can multi-point active region observations aid in forecasting their activity?

296 Placing spacecraft at the triangular Lagrange points provides access to the solar region
 297 behind the solar limb of the spacecraft situated in Sun-Earth L1. This strategic positioning
 298 becomes especially valuable in studying phenomena such as CME-expelled particles that
 299 accelerate through space following the Sun's magnetic field lines. If a spacecraft was located
 300 in L4, it could effectively measure and detect potential dangers in the space environment for
 301 missions, such as manned Lunar and Mars missions. As outlined in Posner et al. (2021), the
 302 additional flare information from Sun-Earth L4 would enable gathering sufficient data to
 303 comprehensively cover all Solar Energetic Particles (SEPs) that could significantly impact
 304 missions in the Earth-Moon system.

305 The improvement in visibility duration resulting from placing additional spacecrafts at
 306 L4 and L5 with $\Theta_{\max} = 60^\circ$ are presented in Table 2 and 3, for L4 and L5 spacecraft in planar-
 307 Lyapunov orbits and 14.5 inclined triangular periodic orbits, respectively (retrieved from
 308 Figure 11). The most significant differences occur between triangular Lagrange point periodic
 309 orbits' inclinations for high latitude observation. Spacecraft placed in L4 periodic orbit
 310 without inclination doubles the visibility duration for high latitudes. However, spacecraft
 311 placed in L4 periodic orbit with a 14.5-degree inclination about the ecliptic with $\alpha =$
 312 0 increases the visibility duration by 131%. When considering the L5 spacecraft, the
 313 improvements become even more substantial (268%).

314 A similar analysis is performed for multi-point, on-disk observation, which measures the
 315 visible duration of a specific latitude observed by two spacecraft. Figure 12 illustrates the
 316 impact of varying Θ_{\max} and the inclination of the periodic orbit on the observation duration
 317 of multi-spacecraft placed in L1, L4, and L5. Unlike Figure 11, the multi-spacecraft view
 318 constraint (visible by two spacecraft at the same time) exhibits significant differences with
 319 respect to the value of Θ_{\max} . This phenomenon arises due to the inherent nature of the
 320 viewing angle differences between L1, L4, and L5, which are separated by 60° . Due to such
 321 separation angle, the overlapping of solar surface on-disk observation begins at $\Theta_{\max} = 30$,
 322 and the overlapping increases as Θ_{\max} increases.

Figure 11: Visibility analysis of solar surface for different latitudes (ϕ) with a varying inclination (i) of triangular Lagrange points and Θ_{\max} using one spacecraft at L1, L4, and L5 (total three spacecraft). Number marks on the contour lines show the observation duration measured in days/year.

Table 2: Solar surface visibility improvements for L1+L4 and L1+L4+L5 planar Lyapunov orbit with $\Theta_{\max} = 60^\circ$ compared to a single spacecraft at L1. Integers cell defines number of averaged visible days per year.

Spacecraft Locations	$\phi = 0^\circ$	$\phi = 20^\circ$	$\phi = 40^\circ$	$\phi = 60^\circ$
L1 (days)	124	120	110	32
L1+L4 (days)	187	182	164	60
Imp. (%)	51%	52%	64%	87.5%
L1+L4+L5 (days)	250	244	228	90
Imp.(%)	101%	103%	128%	181%

Table 3: Solar surface visibility improvements for L1+L4 and L1+L4+L5 (planar Lyapunov orbit for L1 and 14.5 inclination for L4 and L5 periodic orbits) with $\Theta_{\max} = 60^\circ$ compared to a single spacecraft at L1. Integers cell defines number of averaged visible days per year.

Spacecraft Locations	$\phi = 0$	$\phi = 20$	$\phi = 40$	$\phi = 60$
L1 (days)	124	120	110	32
L1+L4 (days)	186	181	153	74
Imp. (%)	50%	51%	53%	131%
L1+L4+L5 (days)	247	242	210	118
Imp.(%)	99%	101%	110%	268%

Number marks on the contour lines show the observation duration measured in days/year.

4.3 Synergy of Multi-Point Solar Limb Observation

Observing the solar limb is critical in reconstructing the solar magnetic field. While on-disk observation provides constraints on the field of the photosphere, solar limb observation data can add constraints on overlying coronal magnetic field structure. This may be crucial for solar magnetic field reconstruction, particularly leading up to solar flares. Unfortunately, up to recently, there has not been an instance where a solar flare was observed simultaneously from both the solar limb and on-disk, as reported by Chen et al. (2020) and Fleishman et al. (2020). Chen et al. (2020) managed to observe on-disk activity four days prior, while Fleishman et al. (2020) observed it two days before the solar flare occurred near the limb. A multi-spacecraft mission strategically positioned at L1, L4, and L5 holds the potential to significantly increase the frequency of observing the solar limb from multiple angles, and from the limb. This advantage stems from the unique geometry of the triangular Lagrange points with respect to the Sun-Earth line.

The visibility condition for solar flares is determined based on the flare loop apex. Figure 13 shows the geometry utilized to determine the solar flare visibility. The figure shows four possible occurrences of the solar flares seen from both bird-eye and spacecraft viewpoints from L1 and L4. From the perspective of spacecraft located at L1, flare *I* represents solar flare occurring within the on-disk observation of the Sun from the spacecraft, which processes large projection effects from the solar surface behind the solar flares. We assume the flare *I* cannot be used as scientific data. Flare *II* represents solar flare with the loop-top source outside the disk but with the footprints inside the on-disk observation. Flare *III* and *IV* represent an invisible solar flare (both footprints and loop-top) as both features are on the other side of the limb. We consider the solar flares with the loop-top visible outside of the solar limb as visible. Hence, solar flare *II* is considered visible, whereas solar flares *I*, *III* and *IV* are considered invisible from L1.

However, when the identical solar flares are viewed simultaneously from spacecraft located in L4, different features of the solar flares are observable, as shown in Figure 13. Except for solar flare *I*, which is still invisible due to the low solar flare loop-top apex, flare *II*, *III*, and *IV* are observable. Solar flare *IV*, which was invisible from the spacecraft at L1, is visible from L4 because of the separation angle of L1 and L4. Flare *IV* represents behind-the-limb solar flare loop-top observation with occulted footprints as the footprints are on the other side of the solar limb. An example of Flare *IV* can be seen in figure 14. Additionally, the solar flares *II* and *III* are observed from different angles, allowing the stereoscopic observation and advancing the 3D reconstruction of the solar flares.

Based on the geometry shown in Figure 13, the minimum and maximum angle of visibility for solar flares with averaged solar flare loop apex of $10,000\text{km}$ (Reale et al. (1997), Reale (2014)) are 80.08 and 99.39 for Θ_{\min} and Θ_{\max} , respectively. Θ_{\min} and Θ_{\max} is calculated as follows

$$\Theta_{\min} = \frac{\pi}{2} - \alpha - \beta \quad (13)$$

$$\Theta_{\max} = \frac{\pi}{2} + \alpha - \beta \quad (14)$$

where α and β is calculated as follows

$$\alpha = \cos^{-1} \left(\frac{r_s}{r_s + h_{apex}} \right) \quad (15)$$

$$\beta = \sin^{-1} \left(\frac{r_s}{AU} \right) \quad (16)$$

where h_{apex} defines the altitude of the solar flare apex, r_s defines the radius of the Sun, and lastly, the AU defines the Astronomical unit, tabulated in table 1. The solar surface coverage with varying colors is plotted in section 6.

Figure 13: Top and spacecraft's view of solar flares erupting from L1 and L5 of the solar surface.

Figure 14: An enormous flare on Feb. 9, 2024, from behind the west limb (W110). The visible flare was magnitude X6.2 with occulted foot points (Case III in Figure 13, image taken from Solar Dynamics Observatory)

367 According to Schrijver et al. (2012), the average number of solar flare events with
 368 energies larger than M1.0 is 140 per year, based on the events recorded from 1996 to 2007
 369 (one solar cycle). Additionally, it is recorded that most of the solar flare events occur within
 370 the $N40^\circ$ and $S40^\circ$. From the simulations plotted in the Appendix section, the solar surface
 371 coverage for stereoscopic coverage is derived as 11.8% and 24% for dual-spacecraft (L1,
 372 L4(or L5)) and triple-spacecraft (L1, L4 and L5) mission, respectively, throughout the year.
 373 Therefore, we can conclude that under the two assumptions: 1) all solar flares have h_{apex}
 374 higher than 10,000km, and 2) all solar flares occur within $N40^\circ$ and $S40^\circ$, placing additional
 375 spacecraft at L4 and L5 will provide multiple-angle on-disk observation and limb observation
 376 of ~ 34 flares per year (Reale et al. (1997), Reale (2014)).

377 4.4 Multi-Point Continuous Sunspot Observation

378 Observing sunspots is essential for advancing solar magnetic field research. However,
 379 observing the long-term evolution of sunspots, from emergence and development to decay,
 380 has been challenging due to the lack of on-disk coverage of the solar surface. This section
 381 aims to elucidate the advancements in the capability of observing sunspots at different
 382 latitudes with a predefined Θ_{max} of 60° for spacecraft pairs of L1+L4 and L1+L4+L5, both
 383 with planar and vertical periodic orbits. Figure 15 depicts the sunspot visibility in days
 384 per solar rotation, which rotates with a differential rotation speed as given by Eq. 4, with
 385 Θ_{max} of 60° . The improvements from placing multiple spacecraft at the triangular Lagrange
 386 points are tabulated in Tables 4 and 5 for 0° and 14.5° inclined triangular Lagrange points,
 387 respectively. As expected, sunspot visibility per solar rotation near the equator of the sun
 388 experiences a 1.5 times improvement for each spacecraft added at L4 and L5, inherent to
 389 the geometry of the triangular Lagrange points with $\Theta_{max} = 60^\circ$. Significant improvements
 390 occur near high-latitude sunspots when inclined periodic orbits are considered. Compared to
 391 placing L4 and L5 spacecraft in a planar orbit, the vertical periodic orbit option improves
 392 sunspot visibility per solar rotation at $\phi = 60^\circ$ by 200%. Interestingly, inclined triangular
 393 Lagrange points exhibit smaller improvement in sunspot visibility per solar rotation for lower
 394 solar surface latitudes ($\phi = 0, 20, 40$). This is due to the nature of the inclined triangular
 395 Lagrange point's latitudinal oscillation motion with respect to the ecliptic plane.

Table 4: Sunspot visibility improvements for L1+L4 and L1+L4+L5 planar Lyapunov orbit with $\Theta_{max} = 60^\circ$ compared to a single spacecraft at L1 in sunspot visibility days per solar rotation.

Spacecraft Locations	$\phi = 0$	$\phi = 20$	$\phi = 40$	$\phi = 60$
L1 (days)	8.0	7.52	5.92	1.6
L1+L4 (days)	11.2	10.56	8.96	2.72
Imp. (%)	40%	40.5%	51%	70%
L1+L4+L5 (days)	14.4	13.76	11.20	3.36
Imp.(%)	80%	82%	89%	110%

Figure 15: Sunspot observation per sidereal differential rotation for different latitude with $\Theta_{\max} = 60^\circ$

Table 5: Sunspot visibility improvements for L1+L4 and L1+L4+L5 (planar Lyapunov orbit for L1 and 14.5 inclination for L4 and L5 periodic orbits) with $\Theta_{\max} = 60^\circ$ compared to a single spacecraft at L1 in sunspot visibility days per solar rotation.

Spacecraft Locations	$\phi = 0$	$\phi = 20$	$\phi = 40$	$\phi = 60$
L1 (days)	8.0	7.52	5.92	1.6
L1+L4 (days)	10.88	10.4	8.48	3.52
Imp. (%)	36%	38%	43%	120%
L1+L4+L5 (days)	14.34	13.44	10.24	4.8
Imp.(%)	78%	79%	72%	200%

5 Summary and discussion

In this study, we conducted a comprehensive analysis of solar surface visibility for a multi-spacecraft mission, aiming to quantify the advantages and disadvantages of various orbit configurations in the Sun-Earth system’s Lagrange points. Our approach involved using the L1 Lyapunov orbit and planar Lyapunov orbit for spacecraft located at L1, and both inclined and planar periodic orbits for the triangular Lagrange points. For a single spacecraft, our analysis showed that placing a spacecraft at the Sun-Earth L4 planar orbit increased on-disk observation by 51% and 87.5% for latitudes $\phi = 0^\circ$ and $\phi = 60^\circ$, respectively. Introducing a spacecraft at Sun-Earth L4 with a 14.5° inclination about the ecliptic plane expanded the observation duration by 131% compared to a single spacecraft at Sun-Earth

406 L1. Furthermore, identical spacecraft placed at L5, mirroring the inclination of the L4
 407 spacecraft, experienced a 268% improvement in observing $\phi = 60^\circ$, compared to a single
 408 spacecraft at Sun-Earth L1. The limb observation, lying within the range of W20 to W40
 409 of the Carrington rotating frame due to the geometry of the triangular Lagrange points,
 410 aligns with on-disk observations from L1 and L4 for $\Theta_{\max} > 30^\circ$. This alignment enhances
 411 the potential for magnetic field reconstruction by combining coronal constraints from limb
 412 observations with on-disk magnetograph observations. Regarding sunspot observation, the
 413 duration significantly increases with additional spacecraft at the triangular Lagrange points.
 414 However, improvements are more substantial in high-latitude observations, with smaller
 415 gains in lower altitudes due to the latitudinal oscillation of inclined triangular Lagrange
 416 points with respect to the ecliptic plane. The implications of these findings are vast for
 417 future heliospheric sciences and human missions to the Moon and Mars. A multi-spacecraft
 418 mission at L4 and L5 enhances our understanding of the Sun and may enable solar activity
 419 forecasting. This information is crucial for spacecraft safety in Earth orbit and future human
 420 missions beyond, providing unprecedented advantages in mitigating potential dangers posed
 421 by solar activity.

P=planar I=Inclined	Solar surface feature coverage	High-latitude coverage	Limb observation
L1	Limited around the Sun-Earth line.	Limited high-latitude coverage.	Limb observation from L1.
L1 + L4(P)	Elongated longitude coverage. Multi-point view starts from $\Theta_{\max} = 30^\circ$. Sunspot observation duration increases.	No increase in high-latitude coverage as L1 and L4 is on the ecliptic plane.	Limb observation from L1 and L4.
L1 + L4(I)	Same as L1 + L4(P). Sunspot observation duration increases. High-latitude sunspots are visible with less projection effect.	Modest increase in high-latitude coverage due to inclined L4 periodic orbit.	Same as L1 + L4(P)
L1 + L4(P) + L5(P)	Larger longitude coverage. Significant increase in sunspot observation	No increase in high-latitude coverage as L4 and L5 are on the ecliptic plane.	Additional limb observation from L5. Multi-point view of L1/4 and L1/5 are covered by limb observation from L5 and L4, respectively.
L1 + L4(I) + L5(P)	Same as L1 + L4(P) + L5(P). High-latitude sunspots are visible with less projection effect.	Modest increase in high-latitude coverage due to inclined L4 periodic orbit.	Same as L1 + L4(P) + L5(P).
L1 + L4(I) + L5(I)	Same as L1 + L4(P) + L5(P). High-latitude sunspots are more frequently visible with less projection effect.	Significant increase in high-latitude coverage duration.	Same as L1 + L4(P) + L5(P).

423 **6 Appendix**

424 The figures in the Appendix section illustrate the visibility condition of the solar surface
425 with multi-spacecraft located in L1, L4, and L5. Figure 16 shows the coverage map of the
426 multi-spacecraft with zero inclination. Figure 17 shows the identical coverage map with
427 14.5° inclined periodic orbit for spacecraft located in the triangular Lagrange points. The
428 Earth's location is projected onto the solar surface with a red dot. The projected location of
429 the L4 and L5 on the solar surface is plotted as red square and diamond, respectively. The
430 visible solar surfaces of the spacecraft are shown in blue, red and green, respectively, for
431 L1, L4 and L5, while the invisible region is in gray. The region visible by two spacecraft is
432 denoted in magenta for L1 and L4, while in cyan for L1 and L5. The white region represents
433 the solar limb viewed from each of the spacecraft. All simulation assumed $\Theta_{\max} = 60^\circ$ for
434 on-disk observation, and $80.08^\circ < \Theta_{\max} < 99.39^\circ$ for limb observation from Sun-Earth L5,
435 which is derived from $h_{apex} = 10,000km$.
